

Video Gain Control/Fader/Multiplexer

The EL4095 is a versatile variable-gain building block. At its core is a fader which can variably blend two inputs

together and an output amplifier that can drive heavy loads. Each input appears as the input of a current-feedback amplifier and with external resistors can separately provide any gain desired. The output is defined as:

$$V_{OUT} = A \cdot V_{INA} (0.5V + V_{GAIN}) + B \cdot V_{INB} (0.5V - V_{GAIN}),$$

where A and B are the fed-back gains of each channel.

Additionally, two logic inputs are provided which each override the analog V_{GAIN} control and force 100% gain for one input and 0% for the other. The logic inputs switch in only 25ns and provide high attenuation to the off channel, while generating very small glitches.

Signal bandwidth is 60MHz, and gain-control bandwidth 20MHz. The gain control recovers from overdrive in only 70ns.

The EL4095 operates from $\pm 5V$ to $\pm 15V$ power supplies, and is available in both 14-pin DIP and narrow surface mount packages.

Pinout

**EL4095
(14-PIN PDIP, SO)
TOP VIEW**

Manufactured under U.S. Patent No. 5,321,371, 5,374,898

Features

- Full function video fader
- 0.02%/0.02° differential gain/phase @ 100% gain
- 25ns multiplexer included
- Output amplifier included
- Calibrated linear gain control
- $\pm 5V$ to $\pm 15V$ operation
- 60MHz bandwidth
- Low thermal errors

Applications

- Video faders/wipers
- Gain control
- Graphics overlay
- Video text insertion
- Level adjust
- Modulation

FIGURE 1. EL4095 IN INVERTING CONNECTION

Stray capacitance at each $-V_{IN}$ terminal should absolutely be minimized, especially in a positive-gain mode, or peaking will occur. Similarly, the load capacitance should be minimized. If more than 25pF of load capacitance must be driven, a load resistor from 100Ω to 400Ω can be added in parallel with the output to reduce peaking, but some bandwidth degradation may occur. A “snubber” load can alternatively be used. This is a resistor in series with a capacitor to ground, 150Ω and 100pF being typical values. The advantage of a snubber is that it does not draw DC load current. A small series resistor, low tens of ohms, can also be used to isolate reactive loads.

Distortion

The signal voltage range of the $+V_{IN}$ terminals is within 3.5V of either supply rail.

One must also consider the range of error currents that will be handled by the $-V_{IN}$ terminals. Since the $-V_{IN}$ of a CFA is the output of a buffer which replicates the voltage at $+V_{IN}$, error currents will flow into the $-V_{IN}$ terminal. When an input channel has 100% gain assigned to it, only a small error current flows into its negative input; when low gain is assigned to the channel the output does not respond to the channel's signal and large error currents flow.

Here are a few idealized examples, based on a gain of +1 for channels A and B and $R_F = 1k\Omega$ for different gain settings:

Gain	V_{INA}	V_{INB}	$I(-V_{INA})$	$I(-V_{INB})$	V_{OUT}
100%	1V	0	0	1mA	1V
75%	1V	0	-250μA	750μA	0.75V
50%	1V	0	-500μA	500μA	0.5V
25%	1V	0	-750μA	250μA	0.25V
0%	1V	0	-1mA	0	0V

Thus, either $-V_{IN}$ can receive up to 1mA error current for 1V of input signal and 1kΩ feedback resistors. The maximum error current is 3mA for the EL4095, but 2mA is more realistic. The major contributor of distortion is the magnitude of error currents, even more important than loading effects. The performance curves show distortion versus input amplitude for different gains.

If maximum bandwidth is not required, distortion can be reduced greatly (and signal voltage range enlarged) by increasing the value of R_F and any associated gain-setting resistor.

100% Accuracies

When a channel gain is set to 100%, static and gain errors are similar to those of a simple CFA. The DC output error is expressed by

$$V_{OUT, Offset} = V_{OS} * A_V + (I_{B-}) * R_F$$

The input offset voltage scales with fed-back gain, but the bias current into the negative input, I_{B-} , adds an error not dependent on gain. Generally, I_{B-} dominates up to gains of about seven.

The fractional gain error is given by

$$E_{GAIN} = (R_F + A_V * R_{IN-}) / R_F + A_V R_{IN-} / R_{OL}$$

The gain error is about 0.3% for a gain of one, and increases only slowly for increasing gain. R_{IN-} is the input impedance of the input stage buffer, and R_{OL} is the transimpedance of the amplifier, 80k Ω and 350k Ω respectively.

Gain Control Inputs

The gain control inputs are differential and may be biased at any voltage as long as \bar{V}_{GAIN} is less than 2.5V below V_+ and 3V above V_- . The differential input impedance is 5.5k Ω , and a common-mode impedance is more than 500k Ω . With zero differential voltage on the gain inputs, both signal inputs have a 50% gain factor. Nominal calibration sets the 100% gain of V_{INA} input at +0.5V of gain control voltage, and 0% at -0.5V of gain control. V_{INB} 's gain is complementary to that of V_{INA} ; +0.5V of gain control sets 0% gain at V_{INB} and -0.5V gain control sets 100% V_{INB} gain. The gain control does not have a completely abrupt transition at the 0% and 100% points. There is about 10mV of "soft" transfer at the gain endpoints. To obtain the most accurate 100% gain factor or best attenuation of 0% gain, it is necessary to overdrive the gain control input by about 30mV. This would set the gain control voltage range as -0.565mV to +0.565V, or 30mV beyond the maximum guaranteed 0% to 100% range.

In fact, the gain control internal circuitry is very complex. Here is a representation of the terminals:

FIGURE 2. REPRESENTATION OF GAIN CONTROL INPUTS V_G AND \bar{V}_G

For gain control inputs between $\pm 0.5V$ ($\pm 90\mu A$), the diode bridge is a low impedance and all of the current into V_G flows

back out through \bar{V}_G . When gain control inputs exceed this amount, the bridge becomes a high impedance as some of the diodes shut off, and the V_G impedance rises sharply from the nominal 5.5k Ω to over 500k Ω . This is the condition of gain control overdrive. The actual circuit produces a much sharper overdrive characteristics than does the simple diode bridge of this representation.

The gain input has a 20MHz -3dB bandwidth and 17ns risetime for inputs to $\pm 0.45V$. When the gain control voltage exceeds the 0% or 100% values, a 70ns overdrive recovery transient will occur when it is brought back to linear range. If quicker gain overdrive response is required, the Force control inputs of the EL4095 can be used.

Force Inputs

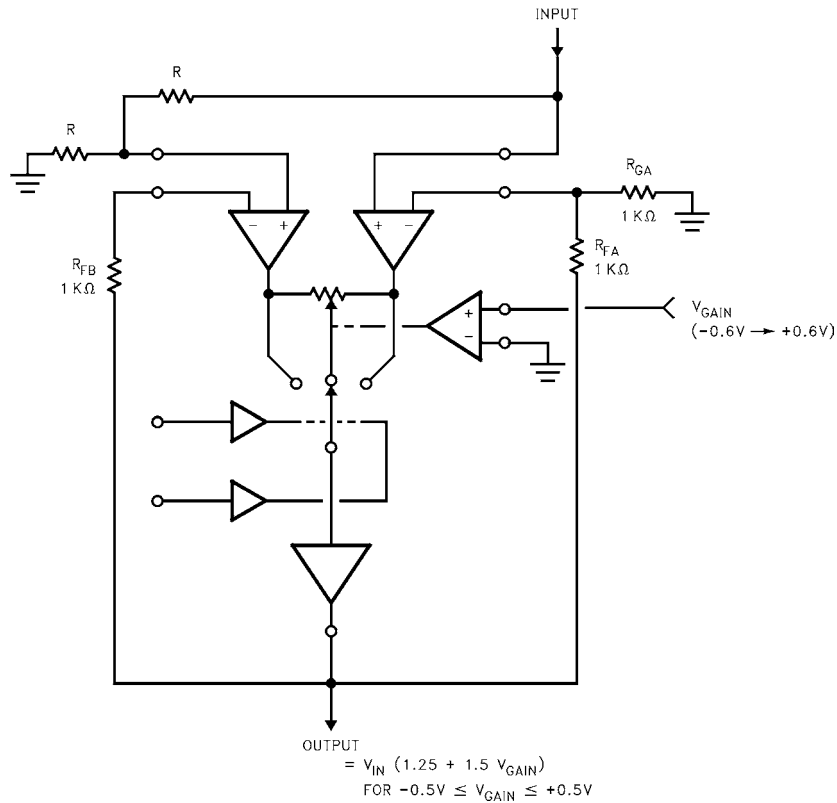

The Force inputs completely override the V_{GAIN} setting and establish maximum attainable 0% and 100% gains for the two input channels. They are activated by a TTL logic low on either of the \bar{FORCE} pins, and perform the analog switching very quickly and cleanly. \bar{FORCEA} causes 100% gain on the A channel and 0% on the B channel. \bar{FORCEB} does the reverse, but there is no defined output state when \bar{FORCEA} and \bar{FORCEB} are simultaneously asserted.

The Force inputs do not incur recovery time penalties, and make ideal multiplexing controls. A typical use would be text overlay, where the A channel is a video input and the B channel is digitally created text data. The \bar{FORCEA} input is set low normally to pass the video signal, but released to display overlay data. The gain control can be used to set the intensity of the digital overlay.

Other Applications Circuits

The EL4095 can also be used as a variable-gain single input amplifier. If a 0% lower gain extreme is required, one channel's input should simply be grounded. Feedback resistors must be connected to both $-V_{IN}$ terminals; the EL4095 will not give the expected gain range when a channel is left unconnected.

This circuit gives +0.5 to +2.0 gain range, and is useful as a signal leveller, where a constant output level is regulated from a range of input amplitudes:

FIGURE 3. LEVELING CIRCUIT WITH $0.5 \leq A_V \leq 2$

Here the A input channel is configured for a gain of +2 and the B channel for a gain of +1 with its input attenuated by 1/2. The connection is virtuous because the distortions do not increase monotonically with reducing gain as would the simple single-input connection.

For video levels, however, these constants can give fairly high differential gain error. The problem occurs for large inputs. Assume that a “twice-size” video input occurs. The A-side stage sees the full amplitude, but the gain would be set to 100% B-input gain to yield an overall gain of 1/2 to produce a standard video output. The $-V_{\text{IN}}$ of the A side is a buffer output that reproduces the input signal, and drives R_{GA} and R_{FA} . Into the two resistors 2.1mA of error current flows for a typical 1.4V of input DC offset, creating distortion in a A-side input stage. R_{GA} and R_{FA} could be increased together in value to reduce the error current and distortions, but increasing R_{FA} would lower bandwidth. A solution would be to simply attenuate the input signal magnitude and restore the EL4095 output level to standard level with another amplifier so:

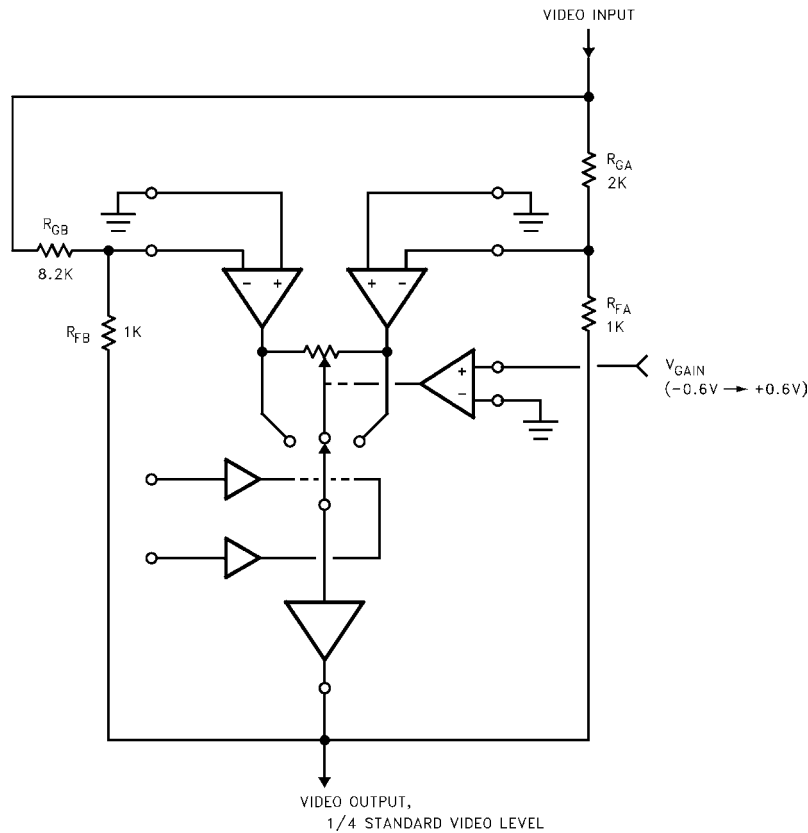

FIGURE 4. REDUCED-GAIN LEVELER FOR VIDEO INPUTS AND DIFFERENTIAL GAIN AND PHASE PERFORMANCE (SEE TEXT)

Although another amplifier is needed to gain the output back to standard level, the reduced error currents bring the differential phase error to less than 0.1 over the entire input range.

A useful technique to reduce video distortion is to DC-restore the video level going into the EL4095, and offsetting black level to -0.35V so that the entire video span encompasses $\pm 0.35V$ rather than the unrestored possible span of $\pm 0.7V$ (for standard-sized signals). For the preceding leveler circuit, the black level should be set more toward -0.7V to accommodate the largest input, or made to vary

with the gain control itself (large gain, small offset; small gain, larger offset).

The EL4095 can be wired as a four quadrant multiplier:

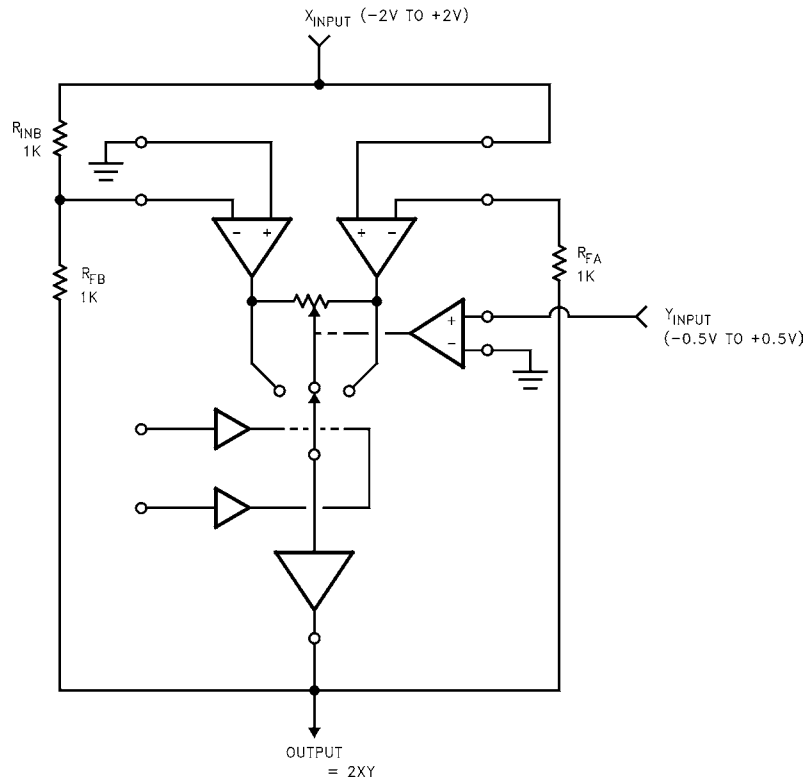

FIGURE 5. EL4095 CONNECTED AS A FOUR-QUADRANT MULTIPLIER

The A channel gains the input by +1 and the B channel by -1. Feedthrough suppression of the Y input can be optimized by introducing an offset between channel A and B. This is easily done by injecting an adjustable current into the summing junction ($-V_{IN}$ terminal) of the B input channel.

The two input channels can be connected to a common input through two dissimilar filters to create a DC-controlled variable filter. This circuit provides a controlled range of peaking through rolloff characteristics:

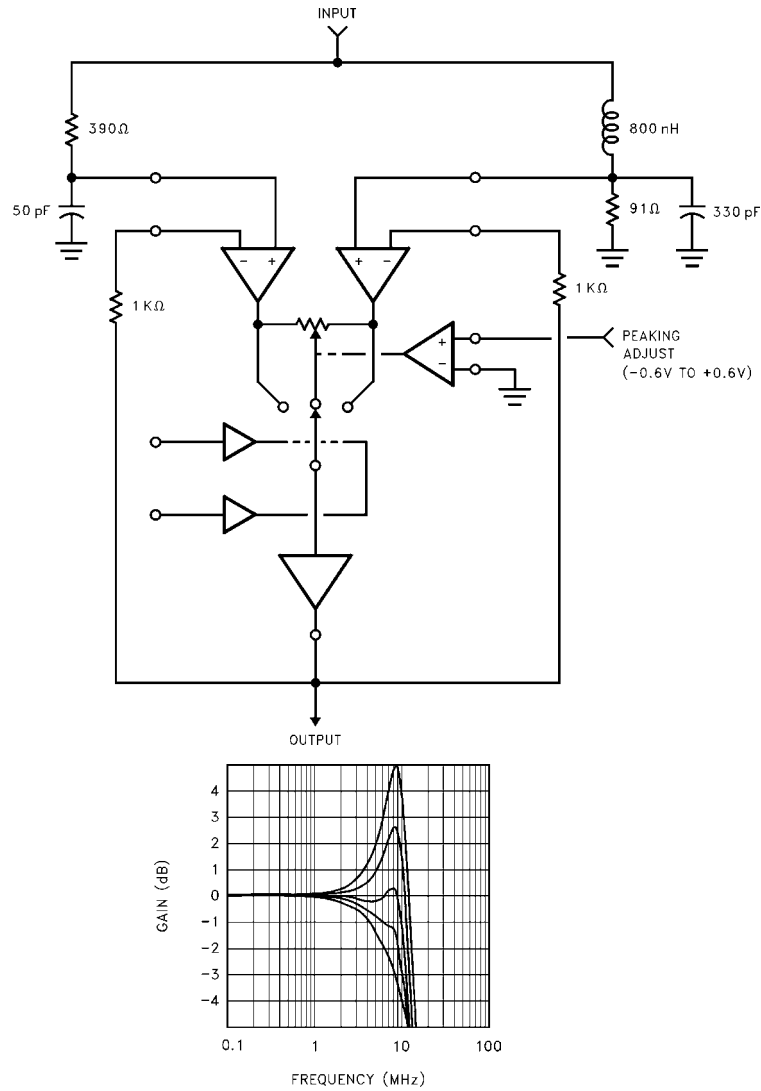

FIGURE 6. VARIABLE PEAKING FILTER

The EL4095 is connected as a unity-gain fader, with an LRC peaking network connected to the A-input and an RC rolloff network connected to the B-input. The plot shows the range of peaking controlled by the V_{GAIN} input. This circuit would be useful for flattening the frequency response of a system, or for providing equalization ahead of a lossy transmission line.

Noise

The electrical noise of the EL4095 has two components: the voltage noise in series with $+V_{\text{IN}}$ is $5\text{nV}/\sqrt{\text{Hz}}$ wideband, and there is a current noise injected into $-V_{\text{IN}}$ of $35\text{pA}/\sqrt{\text{Hz}}$. The output noise will be

$$\overline{V}_{n, \text{out}} = \sqrt{(A_V \times \overline{V}_{n, \text{input}})^2 + (\overline{I}_{n, \text{input}} \times R_F)^2},$$

and the input-referred noise is

$$\overline{V}_{n, \text{input-referred}} = \sqrt{(\overline{V}_{n, \text{input}})^2 + (\overline{I}_{n, \text{input}} \times R_F / A_V)^2}$$

where A_V is the fed-back gain of the EL4095. Here is a plot of input-referred noise vs A_V :

FIGURE 7. INPUT-REFERRED NOISE VS CLOSED-LOOP GAIN

Thus, for a gain of three or more the fader has a noise as good as an op-amp. The only trade-off is that the dynamic range of the input is reduced by the gain due to the nonlinearity caused by gained-up output signals.

Power Dissipation

Peak die temperature must not exceed 150°C. This allows 75°C internal temperature rise for a 75°C ambient. The EL4095 in the 14-pin PDIP package has a thermal resistance of 65°C/W, and can thus dissipate 1.15W at a 75°C ambient temperature. The device draws 20mA maximum supply current, only 600mW at $\pm 15V$ supplies, and the circuit has no dissipation problems in this package.

The SO-14 surface-mount package has a 105°C/W thermal resistance with the EL4095, and only 714mW can be dissipated at 75°C ambient temperature. The EL4095 thus can be operated with $\pm 15V$ supplies at 75°C, but additional dissipation caused by heavy loads must be considered. If this is a problem, the supplies should be reduced to $\pm 5V$ to $\pm 12V$ levels.

The output will survive momentary short-circuits to ground, but the large available current will overheat the die and also potentially destroy the circuit's metal traces. The EL4095 is reliable within its maximum average output currents and operating temperatures.

EL4095 Macromodel

This macromodel is offered to allow simulation of general EL4095 behavior. We have included these characteristics:

Small-signal frequency response	Signal path DC distortions
Output loading effects	V_{GAIN} I-V characteristics
Input impedance	V_{GAIN} overdrive recovery delay
Off-channel feedthrough	100% gain error
Output impedance over frequency	FORCE operation
$-V_{IN}$ characteristics and sensitivity to parasitic capacitance	

These will give a good range of results of various operating conditions, but the macromodel does not behave identically as the circuit in these areas:

Temperature effects	Manufacturing tolerances
Signal overload effects	Supply voltage effects
Signal and $\overline{V_G}$ operating range	Slewrate limitations
Current-limit	Noise
Video and high-frequency distortions	Power supply interactions
Glitch and delay from \overline{FORCE} inputs
